**Abstract**

8     Ultra-low frequency (ULF) waves are regularly observed at Mercury. A recent statistical study showed that the magnetic compressional component is dominant near the magnetic equator and

10    the magnetic transverse component is dominant in the higher magnetic latitude. In this paper, we address possible interpretations of those waves. Because the observed waves typically exhibit

12    linear polarization, they have been considered to be the field-line resonance (FLR) structure. When compressional waves propagate into the inner magnetosphere, they can mode convert to

14    field-aligned waves associated with the ion-ion hybrid resonance. These transverse mode-converted waves oscillate globally reaching high magnetic latitude. Alternatively, the

16    electromagnetic ion Bernstein wave (IBW) has been considered as another possibility because of the strong power of the compressional component. Ray-tracing calculations of the IBW modes

18    propagating in a dipole magnetic field suggest that electromagnetic IBWs are highly unstable to the proton loss cone distribution function with field-aligned group velocity. As the waves

20    propagate they become highly compressional even in a moderate proton $\beta$ plasma. Therefore, the compressional waves near the magnetic equator could be explained by the IBWs while

22    transverse waves could be explained by the FLR concept.

24

## 1. Introduction

26    NASA's Mariner 10 and MESSENGER (MErcury Surface, Space ENvironment, GEochemistry, and Ranging) spacecraft missions provide a wealth of observations within

28    Mercury's magnetosphere [e.g., *Ness et al.*, 1974, *Slavin et al.*, 2008, 2009, *Anderson et al.*, 2008, 2011], and both spacecraft detected ultra-low frequency (ULF) waves in the ion cyclotron

30    frequency range [*Russell*, 1989; *Boardsen et al.*, 2009a, b, 2012].

The first observation of the ULF waves was detected by the Mariner 10 spacecraft during its

32    first flyby. The narrow band waves had frequency $f \sim 0.5$ Hz [*Russell*, 1989] around 40% of the

proton cyclotron frequency $f_{cP} = \Omega_P/(2\pi) \sim 1.31$ Hz. Because heavy ions from solar wind ($H^+$,

34    $He^+$, and $He^{++}$) and planet ($Na^+$, $Mg^+$, and $Si^+$) are abundant in Mercury's magnetosphere [e.g.,

*Zurbuchen et al.*, 2008, 2011; *Raines et al.*, 2013, 2014], the observed wave frequency is clearly

36    located in between heavy ion and proton cyclotron frequencies. Because the signal detected by

Mariner 10 was mainly transverse to the ambient magnetic field ($\mathbf{B}_0$) with an almost linear

38    polarization in the meridian plane, it was suggested that the pulsations were a standing Alfvén

wave along the magnetic field [e.g., *Russell*, 1989; *Othmer et al.*, 1999; *Glassmeier et al.*, 2003,

40    2004; *Kim* and *Lee*, 2003; *Klimushkin et al.*, 2006]. However, unlike transverse Alfvén waves,

the pulsation also had a strong magnetic compressional component, so it was argued that the

42    observed waves could not be pure standing Alfvén waves [*Blomberg*, 1997; *Southwood*, 1997;

*Kim et al.*, 2008].

44    Over 30 years later, highly coherent ULF waves with frequencies near 1 Hz were observed in

Mercury's magnetosphere during the first and second flybys of the MESSENGER spacecraft

46    [*Boardsen et al.*, 2009a, b]. The wave frequency varied between the local $He^+$ cyclotron

frequency ($f_{cHe}$) and the local proton cyclotron frequency. An outbound boundary layer was

48    encountered on both flybys, and wave power was a factor of 10 greater inside the boundary layer

      than outside. Near the closest approach of each flyby trajectory, the power in the wave

50    component oriented parallel to the local magnetic field ( $B_\parallel$ ) tended to be larger than the power

      in the component perpendicular to the field ( $B_\perp$ ), whereas the perpendicular power dominated

52    away from the closest approach.

         More recently, a statistical study of the ULF waves detected in the orbital phase of the

54    MESSENGER spacecraft was made at frequencies in between 0.4 and 5 Hz [*Boardsen et al.*,

      2012]. The survey covered 2.1 Mercury years (March 24 − September 25, 2011). The observed

56    waves can be classified into (a) transverse component dominant (25% of the wave events) and (b)

      compressional component dominant (75% of the wave events).

58       Figure 1 shows an example of the transverse component dominant waves. During this event

         the transverse component ( $B_\perp$ ) was dominant throughout with the wave frequency is almost

60    constant near the 1-2 Hz. Near the magnetic equator, transverse component becomes very strong.

         Thus the waves are close to the local $f_{cP}$ near the magnetic equator and near or below $f_{cHe+}$ at the

62    higher magnetic latitudes. 75% of the wave observations show that the compressional component

       ( $B_\parallel$ ) waves are dominant. Figure 2 shows that the magnetic compression has two peaks near the

64    magnetic equator around 17:10 UT and 17:12 UT, respectively, that straddle the model magnetic

                                          equator.

66    Figure 3 represents another example of ULF waves that show the mixture of transverse

      dominant in the higher latitude and compressional dominant near the equator. In this figure,

68    waves transverse to the local magnetic field were first seen at intermediate magnetic latitudes

      (starting at 35°N), and as the spacecraft approached the magnetic equator the wave amplitude

70    increased and the magnetic compressional component becomes stronger as the frequency

become closer to the local $f_{cP}$. Due to the weakness of Mercury's dipole moment relative to that

72    of Earth's, the magnetic equator location (~1.3 $R_M$, where $R_M$~2440 km is Mercury's radius) can

deviate significantly in latitude from the model, so it is plausible that the compressional peaks in

74    Figure 3 straddle the true magnetic equator.

In the statistical study [*Boardsen et al.*, 2012], the ULF waves are seen at all magnetic local

76    times (MLT), but their observed rate of occurrence is much less on the dayside than the night

side as shown in Figure 4. However, this distribution of wave events could be the lack of

78    coverage near the dayside magnetic equator. The distribution of events peaks near the magnetic

equator and at a radial distance of 1.35 ± 0.13 $R_M$ and drops toward zero as the radial distance

80    increases toward 2$R_M$ (Figure 4)

The polarization characteristics have also been investigated. One of the most dominant

82     features of the wave distribution is that the waves are strongly compressional near the magnetic

equator and transverse far from the equator as shown in an example of wave event in

84     Figure 3. This pattern can be seen in the ratio of parallel component power to total power (

$\left|B_{\parallel}\right|^2 / \left|B\right|^2$ ) for nightside event as shown in Figure 5a. Near the magnetic equator, most values of

86    this power ratio exceed 0.7 ($\left|B_{\parallel}\right|^2 / \left|B\right|^2 > 0.7$), while in the higher magnetic latitude greater than

30°, this power ratio is less than 0.1 ($\left|B_{\parallel}\right|^2 / \left|B\right|^2 < 0.1$). Figure 5b plots the ellipticity versus

88    magnetic latitude for wave events that are strongly transverse. In order to examine ellipticity of

the transverse waves, the ratio of power in the perpendicular component to total power > 0.7

90    (thus $\left|B_{\parallel}\right|^2 / \left|B\right|^2 < 0.3$) has been selected. Near the magnetic equator the absolute value of the

ellipticity is approximately 0.5, whereas at higher magnetic latitudes the absolute value of the

92    ellipticity decreases toward 0 as the waves become more strongly linear.

In order to examine the ULF waves at Mercury, field-line resonance and the electromagnetic

94   ion Bernstein waves (IBWs) have been suggested. Field-line resonances at Mercury are expected

to occur at the ion-ion hybrid (IIH) resonances in the multi-ion plasmas and should have purely

96   transverse polarization [*Kim et al.*, 2008]. When incoming fast compressional waves (FWs)

match the IIH resonance condition, strong absorption of incoming FWs can occur leading to

98   excitation of the IIH resonance [e.g., *Karney et al.*, 1979]. Numerical simulations showed that

this mode-converted IIH waves are guided by the ambient magnetic field line ($\mathbf{B}_0$) and have

100  linear polarization [*Kim et al.*, 2008, 2013, 2015].

On the other hand, *Boardsen et al.* [2012] proposed that the observed waves could be mainly

102  composed of short wavelength (~100 km) electromagnetic IBW mode in a high proton $\beta$ plasma.

Using ray tracing calculations, they confirmed that electromagnetic IBWs generated by loss cone

104  instability can explain MESSENGER observations where the compression straddles the equator

[*Boardsen et al.*, 2014a]. Although the IBWs in the ray tracing calculations can exhibit

106  transverse polarization off the equator, they reflect at magnetic latitudes around 12°, which is

much less than typically observed.

108  In the next sections, we will review both theories and compare the theoretical results with the

observations. The field-line resonance conditions and IBW properties are introduced in Section 2

110  and 3, respectively, and then the last section contains the discussion and summary.

## 2.   Field-Line Resonance at Mercury's Multi-Ion Magnetosphere

112  When $\omega << \omega_{ce}$, $\omega_{pe}$, where $\omega_{ce}$ and $\omega_{pe}$ are the electron gyro- and plasma frequencies, the basic

description of the plasma wave is given by the approximate cold plasma dispersion relation

114  $$n_\perp^2 \cong \frac{(\varepsilon_R - n_\parallel^2)(\varepsilon_L - n_\parallel^2)}{(\varepsilon_S - n_\parallel^2)},$$   (1)

where $n_\parallel$ and $n_\perp$ are refractive indices parallel and perpendicular to $\mathbf{B}_0$ respectively. $\varepsilon_R$, $\varepsilon_L$, and

116 $\varepsilon_S$ are the tensor elements for two ions [*Johnson et al.*, 1995],

$$\varepsilon_R(\varepsilon_L) \cong \frac{c^2}{V_A^2} \frac{\omega_{c1}\omega_{c2}}{\omega_{cut}} \frac{\omega \pm \omega_{cut}}{(\omega \pm \omega_{c1})(\omega \pm \omega_{c2})}, \tag{2}$$

118 $$\varepsilon_S \cong \frac{c^2}{V_A^2} \frac{\omega_{c1}^2\omega_{c2}^2}{\omega_{bb}^2} \frac{\omega^2 - \omega_{bb}^2}{(\omega^2 - \omega_{c1}^2)(\omega^2 - \omega_{c2}^2)}, \tag{3}$$

where $\omega = 2\pi f$ is an angular frequency, $V_A$ and $\omega_{cut}$ are the Alfvén velocity and the cutoff

120 frequency for $\varepsilon_R = 0$ or $\varepsilon_L = 0$, respectively. This approximate dispersion relation has a

resonance when $n_\perp \to \infty$ and two cutoffs when $n_\perp \to 0$. The resonance condition is determined

122 from Eq. (1),

$$n_\parallel^2 = \varepsilon_S, \tag{4}$$

124 and the cutoff conditions are

$$n_\parallel^2 = \varepsilon_{R(L)}. \tag{5}$$

126 The resonance in Eq. (4) is called as the Alfvén resonance, perpendicular ion cyclotron

resonance, or ion-ion hybrid resonance depending on wave frequency. In the MHD

128 approximation, the wave frequency is much lower than the heaviest ion cyclotron frequency, and

Eq. (4) is reduced to the Alfvén resonance,

130 $$\omega_A = k_\parallel V_A, \tag{6}$$

where $k_\parallel$ is a wavenumber parallel to $\mathbf{B}_0$. The resonant absorption of MHD waves in an

132 inhomogeneous magnetosphere has been well investigated [e.g., *Tamao*, 1965; *Uberoi*, 1972;

*Chen* and *Hasegawa*, 1974]. When incident FWs propagate across an Alfvén velocity gradient, it

134 can couple with the shear Alfvén wave, at the location where the phase speed parallel to $\mathbf{B}_0$ is

equal to the local Alfvén speed seen in Eq. (6) and the wave energy is transferred from the FW to

136    a shear Alfvén wave propagating along the magnetic field [*Hasegawa et al.*, 1983]. At Earth's

magnetosphere, because the magnetic field lines are bounded by the ionosphere, shear Alfvén

138    waves have an eigenmode structure along magnetic field lines such that only a discrete spectrum

of frequencies are associated with a field line. Assuming the Alfvén velocity varies smoothly, the

140    frequency of each discrete mode varies continuously across the field lines and this discrete

spectrum of waves is called a field line resonance (FLR) [*Chen and Hasegawa*, 1974, *Southwood*,

142    1974].

By adopting the FLR concept, *Russell* [1989] initially proposed that the detected pulsation

144    from Mariner 10 was a standing Alfvén wave along a background $\mathbf{B}_0$, because the signals were

primarily transverse to $\mathbf{B}_0$. Using an electron density of 3 cm$^{-3}$ and assuming an electron-proton

146    plasma with the measured field strength, he derived an Alfvén velocity of about 1000 km/s. With

a field line length of 4000 km based on a dipole model, *Russell* [1989] also estimated that the

148    fundamental frequency of a standing wave on the field line would be about 0.125 Hz.

Accordingly, the observed 0.5 Hz wave could be the fourth harmonic of the fundamental wave.

150    However, because the observed wave frequency (38% of $f_{cP}$) by Mariner 10 is well outside the

MHD frequency range, the MHD approximation is not applicable for these observations. At

152    higher frequency ($f \sim f_{cP}$), plasma waves should be described using a multi-fluid approach.

For $f \sim f_{cP}$ in an electron-proton plasma, the Alfvén resonance is generalized to the

154    perpendicular ion cyclotron resonance (or Alfvén resonance) from Eq. (4),

$$\omega_A^2 \cong \frac{k_\parallel^2 V_A^2}{(1 - k_\parallel^2 V_A^2 / \omega_{cH}^2)} , \qquad\qquad (7)$$

156    which is the frequency modified Alfvén resonance [e.g., *Stix*, 1992]. At the frequency modified

Alfvén resonance, wave energy transfers from the FW to the shear Alfvén wave and the ion

158    cyclotron wave analogous to the MHD case [e.g., *Karney et al.*, 1979; *Winglee*, 1982; *Kim and*

*Lee*, 2003]. By adopting a two fluid wave model, *Kim* and *Lee* [2003] examined the behavior of

160    the Alfvén resonance when $f \sim f_{cP}$ and discussed the implications for waves at Mercury in a single

ion plasma.

162    When multiple ion species are included in the plasma, there are two additional resonances

between each part of cyclotron frequencies: (a) the Buchsbaum resonance for perpendicular

164    propagation [*Buchsbaum*, 1960], where

$$\varepsilon_S(f_{bb}) = 0,$$    (8)

166    where $f^2_{bb} = f_{c1} f_{c2} (f_{c1} \eta_2 + f_{c2} \eta_1) / (f_{c1} \eta_1 + f_{c2} \eta_2)$ is the Buchsbaum resonance frequency and $\eta_{ion}$

$= N_{ion}/ N_e$ where $N_{ion(e)}$ is an ion (electron) number density and (b) the ion-ion hybrid (IIH)

168    resonances for oblique propagation, [e.g., *Lee et al.*, 2008; *Kim et al.*, 2008] where Eq (4) is

satisfied,

170    $$n_{\parallel}^2(f_{ii}) = \varepsilon_S(f_{ii}),$$    (9)

where $f_{ii}$ is the ion-ion hybrid resonance frequency. At these resonances, the absorption from the

172    FWs to a field-aligned resonant mode occurs, and both resonances provide important features

that have been associated with ULF waves at Earth [e.g., *Johnson et al.*, 1995, *Horne* and *Thorne*,

174    1997, *Johnson* and *Cheng*, 1999, *Lee et al.*, 2008, *Kim et al.*, 2009].

In multi-ion plasmas at Mercury, a necessary condition for resonant mode coupling has been

176    derived and it is the same as the IIH resonance [*Othmer et al.*, 1999; *Glassmeier et al.*, 2003,

2004; *Klimushkin et al.*, 2006]. They had also suggested that the crossover frequency

178    ( $f_{cr}^2 = \eta_1 f_{c2}^2 + \eta_2 f_{c1}^2$ ), is the preferred frequency for the FLR at Mercury when this frequency is

satisfied at the resonance condition, thus $f = f_{ii} = f_{cr}$.

180    Using a model appropriate for the magnetic field and plasma composition at Mercury, *Kim et al.* [2008] demonstrated that FLRs at Mercury should occur when the ion-ion hybrid (IIH) and/or

182    Alfvén resonance conditions are satisfied. Assuming that the plasma inhomogeneity and $\mathbf{B}_0$ lie in $x$ and $z$ direction in the slab coordinate system, respectively, Figure 6 shows time histories of the

184    perturbed electric ($\mathbf{E}$) and magnetic ($\mathbf{B}$) fields at the IIH resonance point in the electron-proton-sodium plasma [*Kim et al.*, 2008]. In this figure, the $E_x$ and $B_y$ component grow in time, while

186    the other wave components ($E_y$, $B_x$, and $B_z$) damp. These results clearly show that the FWs are mode converted into IIH waves near the IIH region where $f \sim f_{ii}$, and the magnetic field of FLRs

188    at Mercury's magnetosphere oscillates linearly in the east-west meridian, which is similar to FLR at Earth [e.g., *Lee and Lysak*, 1989]. Later, these results were extended to the electron-proton-

190    He$^{++}$-Na$^{+}$ plasma [*Kim et al.*, 2013].

       However, in these simulations the inhomogeneity responsible for the mode conversion was a

192    1D inhomogeneity in the heavy ion concentration with a homogeneous magnetic field. More realistically, the mode conversion may also result from the gradient in the magnetic field strength,

194    and 2D effects in dipolar geometry may play an important role especially given the global extent of the wave observations. For inhomogeneous $B_0$ in dipolar geometry, fast wave energy remains

196    most concentrated at the magnetic equator and mode conversion occurs at surfaces of constant magnetic field strength for fixed ion concentrations. Mode conversion primarily occurs at the

198    magnetic equator where the fast mode wave energy concentrates. As the mode converted wave propagates along field lines to regions to higher latitude where the magnetic field strength

200    increases, it encounters the cutoff where $n_{\parallel}^2(f_{bb}) \cong \varepsilon_S(f_{bb}) \to 0$, and ion cyclotron resonance where $n_{\parallel}^2(f_{ci}) \cong \varepsilon_S(f_{cj}) \to \infty$ [*Johnson et al.*, 1989, 1995]. Thus the propagation characteristics

202    of the IIH waves along $\mathbf{B}_0$ will be different from that of homogeneous $B_0$ plasmas, where the

cutoff and resonance would not be encountered. A two-dimensional finite element wave code in

204     multi-fluid plasmas, which solves the full wave equations in global magnetospheric geometry,

has recently been developed [*Kim et al.*, 2015] to explore the effects of inhomogeneity in the

206     magnetic field. Using this code, *Kim et al.* [2015] investigated how field-aligned propagating

ULF waves at Mercury can be generated by externally driven FWs via mode conversion at the

208     IIH resonance and how such waves globally oscillate.

Figure 7 shows the wave solutions from the 2D wave model [*Kim et al.*, 2015]. In this figure,

210     both the FW and the mode-converted IIH wave modes are clearly seen. The FW mode appearing

in all electromagnetic components is directly launched near $(r_{ext}, z_{ext}) = (2 \, R_M, 0)$ and propagates

212     away from the source toward the inner and outer magnetosphere. Because the FW mode is

launched near the magnetic equator (point A in Figure 7b), the waves propagating toward the

214     inner magnetosphere partially reflect near $r/R_M = 1.43$, where the cutoff condition of the FW

mode is satisfied (point B in Figure 7b). The remainder of the energy penetrates deep into the

216     magnetosphere and totally reflects at Mercury's surface due to the reflecting boundary condition.

The FWs reflected from Mercury's surface propagate to the outer magnetosphere with different

218     propagation angle (point C in Figure 7b) and are eventually absorbed near the outer boundary. A

numerical collisional layer has been added near the outer boundary to ensure that outgoing waves

220     do not reflect back into the domain.

On the other hand, the IIH resonant waves appear only in $E_\eta$, $E_b$, and $B_\varphi$ in Figure 7, where

222     the unit vector $\hat{b}$ is along the magnetic field line, $\hat{\varphi}$ is the azimuthal direction, and $\hat{\eta}$ is normal

to the field line pointing outward. In this figure, IIH waves show long wavelength in the field-

224     aligned direction and fine structure in the perpendicular direction for $1.4 < L_M < 1.8$, where $L_M$ is

Mercury's L-shell. Because the waves launched at $L_M=2$ are pure FW modes, the waves showing

226     field-aligned structures in $E_\eta$ and $B_\varphi$ are unmistakable evidence of mode conversion.

In Figure 7, *Kim et al.* [2015] also over-plots the locations where $f = f_{bb}$, which corresponds to

228     the cutoff of the field-aligned propagating IIH waves. Waves at larger radial distance encounter

the cutoff location before they reach higher latitude, but because the mode converted wave is

230     able to penetrate the evanescent region between Buchsbaum resonance to the ground, wave

power can reach the surface where it reflects and sets up a global oscillation similar to the field-

232     line resonance at Earth [e.g., *Lee* and *Lysak*, 1989], although it is weakly damped Conversely,

field-line resonance occurs at Mercury when the IIH resonance conditions are satisfied [e.g., *Kim*

234     *et al.*, 2008], and because such resonances globally oscillates, they reach higher magnetic

latitudes.

236     In order to determine how efficiently wave absorption occurs at Mercury, *Kim et al.* [2011]

evaluated the absorption coefficients at the IIH resonance for variable concentrations of sodium

238     ($\eta_{Na}$) and azimuthal ($m_y$) and field aligned wave harmonic numbers ($m_z$) using 1D full wave

model. They found that the absorption at the IIH resonance occurs for a broad range of

240     parameters of $\eta_{Na}$, $m_y$, and $m_z$, and is also very sensitive to wave number and the ion

concentration ratio. Thus they suggested that the radial profile of field-line resonances at

242     Mercury can exhibit complex, discontinuous structure.

In order to examine wave absorption in the various L-shell, using a 1D full wave model [*Kim*

244     *et al.*, 2011], we also calculate the absorption coefficient as a function of (a) $L_M$ and $\eta_{Na}$ for $f =$

0.95 Hz and (b) $\Omega = f / f_{cP}$ and $\eta_{Na}$ at $L_M = 1.75$ for $m_y = 0$ as shown in Figure 8. The figure

246     clearly shows that strong absorption occurs in a wide range of $\eta_{Na}$, $L_M$, and $\Omega$, which is

consistent with *Kim et al.* [2011]. The results can be summarized as: strong absorption occurs (a)

248 where $1.4 \leq L_M \leq 1.8$ for $\eta_{Na} = 15\%$ and $f = 0.95$ Hz in Figure 8a, which is consistent with the 2D

full wave calculation in Figure 7 (b) where $0.1 \leq \Omega \leq 0.65$ for $L_M = 1.75$ and $\eta_{Na} = 15\%$ in Figure

250 8b, and (c) where $7\% < \eta_{Na} < 49\%$ for $L_M = 1.75$ and $f = 0.95$ Hz in Figure 8a-b. Because the

absorption of FW modes corresponds to the generation of IIH waves, it has been suggested that

252 IIH waves detected by spacecraft can be used to infer heavy ion density ratio [*Kim et al.*, 2008;

*Kazakov* and *Fülöp*, 2013]. However, strong absorption in a wide range of $\eta_{Na}$ at a single

254 magnetic field line in Figure 8 leads to the conclusion that the heavy ion density ratio cannot be

simply inferred from the frequency of field-aligned IIH waves at Mercury.

256  In this section, we introduce how field-aligned propagating ULF waves at Mercury can be

generated by externally driven FWs via mode conversion at the ion-ion hybrid resonance. The

258 mode-converted IIH waves are strongly guided by $\mathbf{B}_0$ and have linear polarization. Simulations

in dipole magnetic field show how IIH waves can reach higher magnetic latitudes over 40° for

260 realistic magnetic field and densities at Mercury and how they globally oscillate. These results

are consistent with the observed waves that can propagate over magnetic latitude of 40° with

262 strong magnetic transverse component and linear polarization seen in Figure 1-2 [*Boardsen et al.*,

2012]. Simulations also show that mode conversion occurs in a wide range of L-shell for a single

264 frequency wave, which is also consistent with wave observation. For instance, strong transverse

waves near 1 Hz are found in $1.3 \leq L_M \leq 1.8$ and $0 < MLT < 42°$ by both observation (Figure 1) and

266 simulation (Figure 7).

## 3. Ion Bernstein Waves

268  Although the concept of FLR can explain many of these observations, strong magnetic

compressibility cannot be explained by this theory. The mixture of compressional waves and the

270 mode converted waves may occur, but FLR cannot explain the waves that are compressionally

dominant ($\left|B_\parallel\right|^2/\left|B\right|^2 > 0.5$), about ~75% of all observations [*Boardsen et al.*, 2012]. These

272            waves can have up to 4 harmonics (Nyquist frequency limited). Figure 2 and

Figure 3 show examples of waves that are highly compressional near the magnetic equator. In

274    these figures, it should be noted that the magnetic compression maximizes slightly away from

equator (with maxima straddling the equator). In Figure 3 the "true equator" crossing is believe

276    to be shifted from the model equator crossing, the minimum in $B_0$ occurs around 2:38UT.

We summarize the results of the wave propagation study of the ion-Bernstein wave (IBW)

278    mode by *Boardsen et al.* [2014a]. *Boardsen et al.* [2012] proposed that these highly

compressional waves are IBW mode waves in a high proton $\beta$ plasma (~2). For the observed

280    values of $\beta$ *Denton et al.*[2010] noted that the IBW mode around peak growth rate develops a

strong magnetic compression. However, based on an analysis of data obtained from the plasma

282    instrument on the MESSENGER spacecraft it was shown that the proton $0.1<\beta<0.5$ in the

regions where these waves are observed [*Boardsen et al.*, 2014a], with proton $\beta$ in the range 0.1

284    to 0.2 near 1.35 $R_M$, where the occurrence peaks in Figure 4c. In this range the IBW mode

around the peak growth rate shows weak to moderate compression [*Denton et al.*, 2010; *Gary et*

286    *al.*, 2010].

Because the occurrence of these compressional waves peaks around 1.35 $R_M$, large planetary

288    loss cones are expected and have been found in the proton data [*Boardsen et al.*, 2014a]. At these

radial distances on the nightside typical values for the proton density are $1-3$ cm$^{-3}$ with

290    temperatures around 1 keV. Mercury has no plasmasphere, due to the lack of and ionosphere and

a very weak co-rotational electric field, therefore the cold plasma contribution to the ion

292    population is believed to be negligible. Of course if there were a cold plasma component present,

then these waves could be explained by the "fast magnetosonic mode" which is strongly

294     compressional [*Boardsen et al.*, 2014b] and its dispersion relation is given by the extraordinary

      mode in cold plasma theory [*Stix*, 1992].

296       Figure 9a shows the proton distribution function where the loss cone distribution is

      approximated by the difference of two bi-Maxwellians with a $\beta$ of 0.135 used as input to the

298     warm plasma dispersion solver WHAMP (Waves in Homogeneous Anisotropic Multi-

      component Magnetized Plasma) [*Rönnmark*, 1982]. The black dot with the vertical bar in Figure

300     9a, which lies in a region with positive perpendicular gradient, indicates where the protons in

      velocity space strongly interact with waves at maximum growth rate (point A in Figure 9b). The

302     index of refraction curve that contains maximum growth rate is plotted on top of the

      growth/damping rate of the dispersion surface. Around the peak growth rate the solution is

304     consistent with solutions found in the Earth's plasma sheet boundary layer [*Denton et al.*, 2010;

      *Gary et al.*, 2010]. The branch of the index of refraction surface labeled A-B in Figure 9b is

306     characterized by strong growth with weak to moderate magnetic compression, consistent with

      the findings of *Denton et al.*[ 2010] and *Gary et al.* [2010]. The branch labeled B-D in Figure 9b

308     is characterized by weak damping and strong magnetic compression. On branch A-B, $k_{\parallel}V_{G\parallel}$ is

      positive ($k_{\parallel}V_{G\parallel} > 0$), while on branch B-D, $k_{\parallel}V_{G\parallel}$ is negative ($k_{\parallel}V_{G\parallel} < 0$), where $V_{G\parallel}$ is the group

310     velocity parallel to $\mathbf{B}_0$. This fact is important in understanding the strange cyclic propagation

      behavior of the waves in magnetic latitude shown in Figure 10.

312       *Boardsen et al.* [2014a] called these waves the IBW mode because the wave vector is nearly

      perpendicular to the background magnetic field, the wave electric field is strongly aligned in the

314     wave vector direction, and the peak wave growth is near a harmonics of the proton cyclotron

      frequency. As noted by *Denton et al.* [2010] and *Boardsen et al.* [2014a], these waves are not

316     electrostatic because the $E/(cB)$ ratio is below one ($E/(cB) < 1$), peaking around 0.25 at the

maximum compression. It is pointed out that the phase velocity of this mode is ~100 km/s

318    compared to a proton thermal speed of ~1000 km/s so the real part of the dispersion relation

cannot be approximated by cold plasma theory for these short wavelength waves of ~100 km.

320    Using RATRACE [*Rönnmark*, 1984], warm plasma ray tracing of this mode was performed by

*Boardsen et al.* [2014a] as shown in Figure 10. In this preliminary study, they assumed an

322    electron-proton plasma with a constant density and dipole magnetic field throughout the ray-

tracing volume. The ray was launched with a wavevector and frequency consistent with the peak

324    growth rate at the magnetic equator. The group velocity for this mode is highly field-aligned

except around points B and D in Figure 9b (if the index of refraction surface were drawn to scale

326    it would appear as horizontal line in Figure 9b and for weak dissipation the group velocity is

perpendicular to the index of refraction surface).

328    The ray launched at the magnetic equator (with peak growth rate at point A in Figure 9b)

propagates away from the equator. As the ray moves outwards in magnetic latitude in Figure 10a,

330    its location on the index of refraction surface slides toward point B in Figure 9b.  As the ray

moves around point B onto the B-D segment of the index of refraction surface $V_{G\parallel}$ changes sign

332    (the sign of $k_\parallel$ does not change) and the ray starts to propagate back toward the magnetic equator.

The "cusp like" shape of the reflection point in Figure 10 is due to the "cusp like" shape of the

334    index of refraction surface at point B in Figure 9b.

If the ray reaches point D in Figure 9b on the index of refraction surface before reaching the

336    equator the sign of $V_{G\parallel}$ will change as $k_\parallel$ goes through zero and the wave will start to propagate

away from the magnetic equator on the D-B segment. When point B in Figure 9b is reached on

338    the index of refraction surface the sign of $V_{G\parallel}$ changes sign again and the ray propagates back to

the magnetic equator on the B-A segment and continues into the southern hemisphere where this

340    strange cyclic behavior repeats in the other hemisphere.

Of course the shape of index of refraction surface will change as the ray propagates. For this

342    simple model, *Boardsen et al.* [2014a] found that the index of refraction surface retained the

general features shown in Figure 9b, a segment A-B with large growth rate and moderate

344    compression and a segment B-D with near zero damping and large compression, and a sharp

cusp formed by the intersection of the curves A-B and B-D. For higher proton $\beta$ around 0.5

346    *Boardsen et al.* [2014a] found another cycle where compression peaks upon crossing the

magnetic equator, but in general the proton $\beta$ tends to be around 0.1 to 0.2 where the majority of

348    the compressional waves observations are observed.

*Boardsen et al.* [2014a] also found that the group velocity drops as the waves propagate

350    through peak compression leading to a pile-up of compressional wave energy density. Looking at

Figure 10a one sees compression peaking off the magnetic equator at $\pm 7°$ consistent with the

352    observations. They also found that the wavelength is much smaller than the spatial scale lengths

suggesting that the WKB approximation is reasonable, but they pointed that in principle the pile

354    up of the wave energy while propagating through peak compression could violate the WKB

approximation, and studies using full wave solutions are needed around peak compression.

356    The observed wave frequency ratio to the proton cyclotron frequency ($\omega/\Omega_p$) for the

fundamental of 3 events studied by *Boardsen et al.* [2014a] were between 0.63 and 0.76 near

358    peak compression, while theory predicts at peak growth that this ratio is between 0.93 and 0.97

(depending on electron temperature) for the parameter range used in their study. *Boardsen et al.*

360    [2014a] pointed out that at peak linear growth rate the perpendicular component of the group

velocity $V_{G\parallel}$ is ~40 km/s. The magnitude of $V_{G\parallel}$ lies in the range of the $E \times B$ drift velocity based

362     on estimates of the cross-tail electric field [*DiBraccio et al.*, 2013]. If $V_{G\parallel}$ is directed against the

        drift velocity their sum could be small leading to optimal growth in Mercury's frame of

364     reference. For this orientation one predicts a Doppler shift that can explain this discrepancy.

        They also noted that $\omega/\Omega_P$ drops to 0.8 at peak compression which can account for about 1/2 of

366     the difference.

        Here, we reviewed the interpretation that the strong magnetic compressional waves near $f_{cP}$

368     and its harmonics observed with 20° of Mercury's magnetic equator could be the IBW mode.

        *Boardsen et al.* [2014a] show that the proton loss-cone distributions are highly unstable to the

370     IBW mode. They found that the index of refraction surface, where the maximum growth rate

        appears, is composed of two line segments, one segment consists of high growth rate and low

372     magnetic compression, and the other branch consists of small damping rate and is highly

        compressional (Figure 9b). As the IBW mode propagates in magnetic latitude (Figure 10) they

374     switch between the branches. For the dominate mode of cyclic propagation the compression

        maximizes at ±7° about the magnetic equator consistent with the observation of many equatorial

376     crossings by MESSENGER (e.g., Figure 2). At peak compression the group velocity drops

        which would lead to a pile up of compressional wave energy.

378     *Boardsen et al.* [2014a] reconciled the difference between linear modeling $\omega/\Omega_P$ at the model

        peak growth rate and the observed $\omega/\Omega_P$ around peak compression as due to the Doppler shift.

380     They also point out that about 1/2 the difference can be accounted for by the change in this ratio

        as the wave propagates from peak growth rate to peak compression (Figure 10).

382     **4.   Discussion and Summary**

        In this review, we provided a brief overview of the observed characteristics of ULF waves at

384     Mercury. A recent statistical study of ULF waves at Mercury based on MESSENGER data

[*Boardsen et al.*, 2012] reported the occurrence and polarization of the detected waves. The

386    waves are usually observed between radial distances of 1.1 to 1.8 $R_M$ with maximum occurrence

near $R_M \sim 1.4$ and between magnetic latitudes of $\pm 40°$ with strong occurrence near the magnetic

388    equator. These waves are also detected primarily on the night side with two maximum peaks

around MLT 6 and 21. Measurements of wave polarization indicate that the waves are mostly

390    compressional near the magnetic equator, but the transverse component is dominant at latitudes

greater than $\sim 20°$. The transverse fluctuations are also linearly polarized.

392        We also introduced the field-line resonance and the electromagnetic ion Bernstein waves to

explain such waves and we showed that both theories can partially explain the observations.

394    When the FW mode is launched in the outer magnetosphere, the waves propagate to inner

magnetosphere and strong field-aligned waves are mode-converted at the IH resonance. Such

396    mode-converted IIH waves globally oscillate, and thus reach higher magnetic latitude with

transverse and linear polarization, which is consistent with observations at higher magnetic

398    latitude. The ray-tracing calculations explored the propagation of the IBW mode in a dipole

magnetic field and found that the electromagnetic IBWs are highly unstable to the proton loss

400    cone distribution function and the wave's group velocity is highly field aligned. As the waves

propagate they can become highly compressional even in a moderate proton $\beta \sim 0.05$ to 0.54

402    plasma. Therefore, the compressional waves near the equator and transverse waves in the higher

latitudes can be explained by IBWs and FLR, respectively.

404        Although both theories obtained general characteristics of waves detected at Mercury, much

work remains. First, *Kim et al.* [2008, 2015] used a cold plasma model even though kinetic

406    effects in hot plasmas are believed to be important for the generation and propagation of ULF

waves at Mercury [e.g., *Glassmeier et al.*, 2003; *Slavin et al.*, 2009; *Boardsen et al.*, 2012,

408    2014a]. In hot plasmas, the FW mode can be converted into the short wavelength IBW or ion

cyclotron wave modes (or their higher harmonics) at the IIH resonance [e.g., *Wukitch et al.*,

410    2005]. The mode-converted IBW modes have short-wavelength in the radial direction and long-

wavelength in field-aligned direction, thus the mode-converted IBW mode is expected to

412    propagate at large normal angle because of $k_\perp >> k_\parallel$. Therefore, a short wavelength IBW mode

at Mercury could be either externally generated via mode conversion at the IIH resonance or

414    internally generated from plasma instability [*Boardsen et al.*, 2014a]. It should be noted that the

wave occurrence is much higher near the magnetic equator than off the equator and wave

416    characteristics at higher latitude are mainly transverse while near the equator the waves are

strongly compressible. Thus the compressionally dominant waves near the magnetic equator

418    could be mixed with internally generated and externally mode-converted IBW modes while

waves at higher magnetic latitudes could be mode-converted IIH waves (or IBWs).

420        At Mercury, various heavy ion species, such as $He^+$, $He^{++}$, $Na^+$, $Mg^+$, and $Si^+$, are abundant.

However, previous studies used a simple plasma density model. *Kim et al.*, [2015] assumed

422    electron-proton-$Na^+$ plasmas with constant $Na^+$ density ratio. When lighter ions ($He^+$ and $He^{++}$)

are included, the cutoff condition of the field-aligned waves (the Buchsbaum resonance) shifts

424    toward the outer magnetosphere and lower magnetic latitude. In addition, depending on the

heavy ion density ratios, the wave stop gap between the locations where $f = f_{bb}$ and $f = f_{ci}$

426    becomes wider or narrower. Figure 11 shows the dispersion relation ($n_\parallel^2 = \varepsilon_S$) of the IIH waves

along the magnetic field line at $L_M$=1.4 for 2% and 15% $He^{++}$ or 15% $Na^+$ plasmas and the stop

428    gap between $f_{bb}$ and $f_{cHe++}$ is clearly seen in this figure. For electron-proton-$He^{++}$ plasmas, the

wave stop gap width increases as $He^{++}$ density increases. Thus waves in a 2% $He^{++}$ plasma might

430    be able to tunnel through the stop gap whereas waves could be localized near the magnetic

equator for a 15% He$^{++}$ plasma because the stop gap is impenetrable. In contrast, the waves do

432    not reach the cut off or resonance locations for Na 15% plasmas and the waves can reach the

higher magnetic latitude easily. Therefore, the mode-converted waves can tunnel through the

434    wave stop gap similar to left-handed polarized EMIC waves at Earth [*Johnson et al.*, 1989, 1995;

*Johnson* and *Cheng*, 1999] or localized between Buchsbaum locations [*Kim et al.*, 2009]

436    depending on wave tunneling effects.

The preliminary ray-tracing calculations of IBW mode were performed using an electron

438    proton plasma without heavy ion effects. However, He$^{++}$ is believed to be one of the primary ion

species present at Mercury. Because Bernstein waves are excited near the harmonics of the

440    heavy ion cyclotron frequencies when heavy ions are included [e.g., *Stix*, 1992] and the detected

wave frequencies are located in the range between $f_{cHe++}$ and $f_{cP}$, the heavy ion effects should also

442    be included on the ray-tracing calculations for the IBW mode.

Both the 2D full wave and the ray-tracing calculations also assumed a simple dipole magnetic

444    field model with azimuthal symmetry, whereas the observations shows strong asymmetry

structure in MLT on their occurrence. In addition, the 2D full wave calculations also assume a

446    perfectly conducting boundary condition at Mercury's surface rather than realistic conductivity

at the surface [*Anderson et al.*, 2014]. Because the boundary condition with finite conductivity

448    can damp the field-line resonance at Earth [*Lee and Takahashi*, 2006], the realistic boundary

condition might be important in Mercury's magnetosphere.

450    Additionally, even though the wavelength is much smaller than the scale length, *Boardsen et*

*al.* [2014a] noted that the sharp drop in group velocity which leads to the pile up of magnetic

452    compressional wave energy probably violates the WKB approximation so full wave modeling is

required around the peak compression and the turning points. Existing ray tracing models

454   typically ignore spatially varying bulk flow velocities and in general cannot handle tunneling and

mode conversion. Therefore, although the ion Bernstein mode explanation can qualitatively

456   explain the compressional observations, further quantitative analysis is required to provide better

comparisons with data.

458   Finally, it is necessary to extend the statistical study from *Boardsen et al.* [2012] using more

recent magnetic field data from MESSENGER. With the evolution of the MESSENGER orbit

460   over time, the spatial coverage of the inner magnetosphere is significantly better than that used in

*Boardsen et al.* [2012], which covered only a few months after orbital insertion. The better

462   coverage allows us to compare the statistics directly at the magnetic equator and along a field

line, similar to statistical study of EMIC waves at Earth [e.g., *Min et al.*, 2012], as opposed to

464   having to map observations as was done with the more limited coverage in the previous study.

610

Figure 1. An example of a ULF wave for which the transverse component was dominant at all latitudes, even during equatorial passage. Dynamic spectra of the (top) parallel (compressional) and (middle) perpendicular (transverse) components and (bottom) degree of polarization (DOP) of the magnetic field are shown on August 1 2011. The vertical black line indicates the model magnetic equator. The white curves show the (top to bottom) $H^+$, $He^{++}$, and $He^+$ cyclotron frequencies. The time-axis label L-SHELL is the magnetic L-shell, M-LAT is magnetic latitude in degrees, MLT is magnetic local time in hours, R is the radial position of the spacecraft from planet center in $R_M$, and R* is the radial distance from the offset dipole. Narrow-band harmonic waves are observed in all panels. (Adapted from *Boardsen et al.* [2012])

620
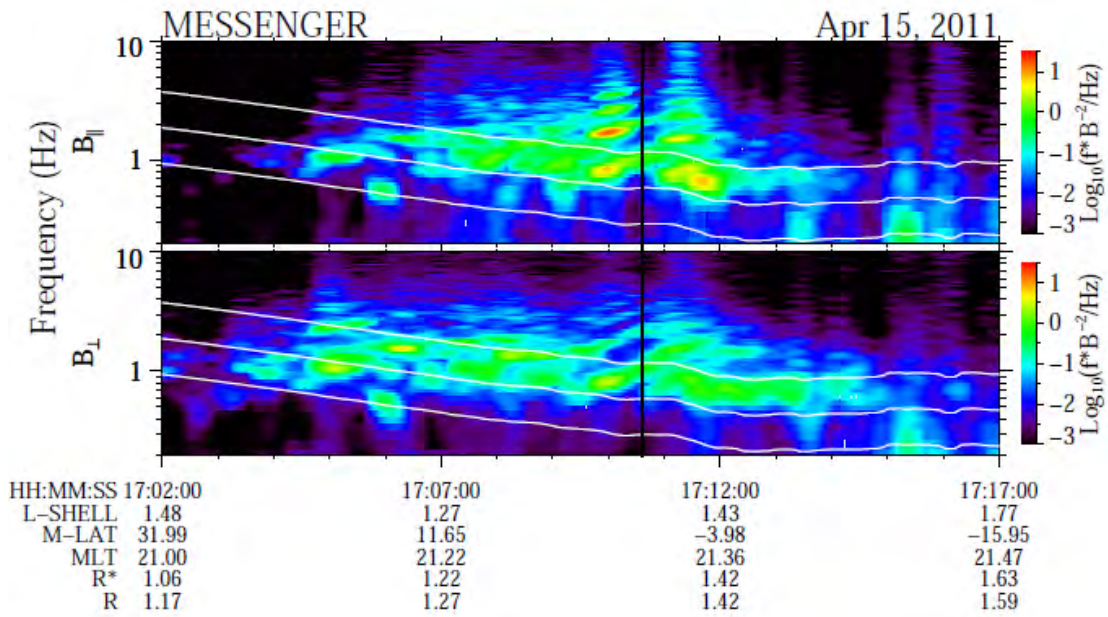

Figure 2 An example of a ULF wave for which the compressional component was dominant near the crossing of the model magnetic equator. Note that the magnetic compression straddles the model magnetic equator. (Adapted from *Boardsen et al.* [2012])

628

630    Figure 3. An example of ULF waves which are highly compressional near the magnetic equator

and transverse away from the magnetic equator. The magnetic compression has a peak around

632    02:36 UT and another peak around 2:42 UT. The magnetic minimum (indicated by the dip in the

cyclotron   frequencies)   is   around   02:38   UT   suggesting   the   location   of   the

634    "true" magnetic equator crossing. (Adapted from *Boardsen et al.* [2012])

636

Wave Events Normalized by Coverage

638   Figure 4. Histograms of wave events normalized by coverage as a function of (a) magnetic local

time, (b) magnetic latitude, and (c) radial distance (Adapted from *Boardsen et al.* [2012])

640

642

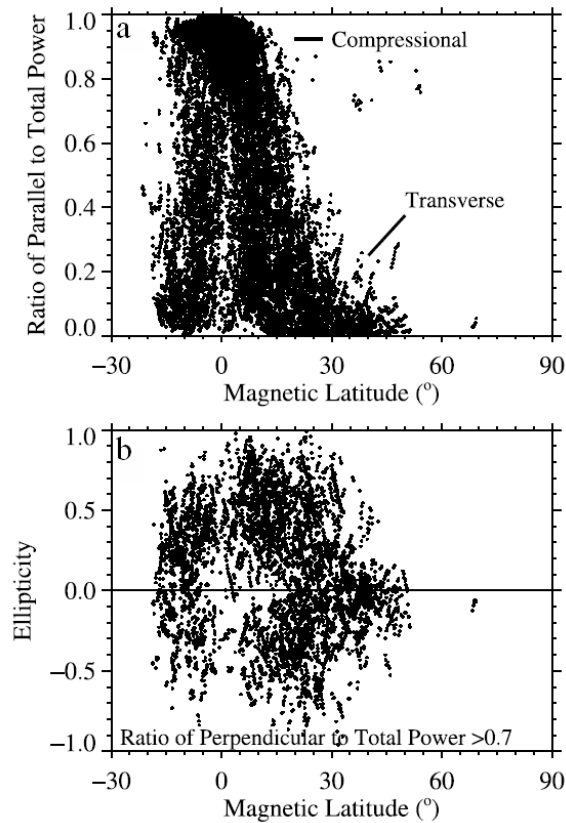

Figure 5. (a) Ratio of parallel power to total power versus magnetic latitude for nightside wave

events. The waves tend to be compressional near the equator and strongly transverse away from

the equator. (b) Wave ellipticity versus magnetic latitude for wave events for which the ratio of

transverse power to total power is greater than 0.7 (Adapted from *Boardsen et al.* [2012])

648
650

Figure 6. (a–e) Time histories of electromagnetic fields and (f) the Poynting flux S of wave at

652    the IIH resonance marked as diamond for $f/f_{cP} = 0.2$. In Figure 6f, the dotted, dashed, and solid

lines are $S_x$, $S_y$, and $S_z$, respectively. In this figure, the slab coordinate has been adopted assuming

654    that the plasma inhomogeneity and $\mathbf{B}_0$ lie in $x$ and $z$ direction, respectively. (Adapted from *Kim et*

*al.* [2008])

656
658

Figure 7. Wave solutions if (a-c) electric field and (d-f) magnetic field. Here, $\hat{\mathbf{b}}$ is along the

660 magnetic field line from north to south, $\hat{\boldsymbol{\varphi}}$ is the usual azimuthal direction and $\hat{\boldsymbol{\eta}}$ is normal to the

field line pointing outward ($\hat{\boldsymbol{\eta}} = \hat{\mathbf{b}} \times \hat{\boldsymbol{\varphi}}$), with the assumption of $\mathbf{B}_0 \cdot \hat{\boldsymbol{\varphi}} = 0$. The solid lines indicate

662 $\omega = \omega_{ci}$, the dashed-dotted lines indicate $\omega = \omega_{bb}$, and the dashed lines are magnetic field line at

$L_M = 1.5$ and 2.0, respectively. The circle represents where $\omega = \omega_{L0}$, the FW mode cutoff location

664 at the magnetic equator. (Adapted from *Kim et al.* [2015])
666

Figure 8. The absorption coefficient as a function of (a) $L_M$ and $\eta_{Na}$ and (b) $\Omega = f / f_{cP}$. The

668    horizontal dashed lines represent where $\eta_{Na} = 15\%$, which is the same condition as 2D full wave

calculations [*Kim et al.*, 2015] and the vertical dashed lines are where $L_M = 1.75$ in (a) and $f =$

670    0.95 Hz in (b), respectively.
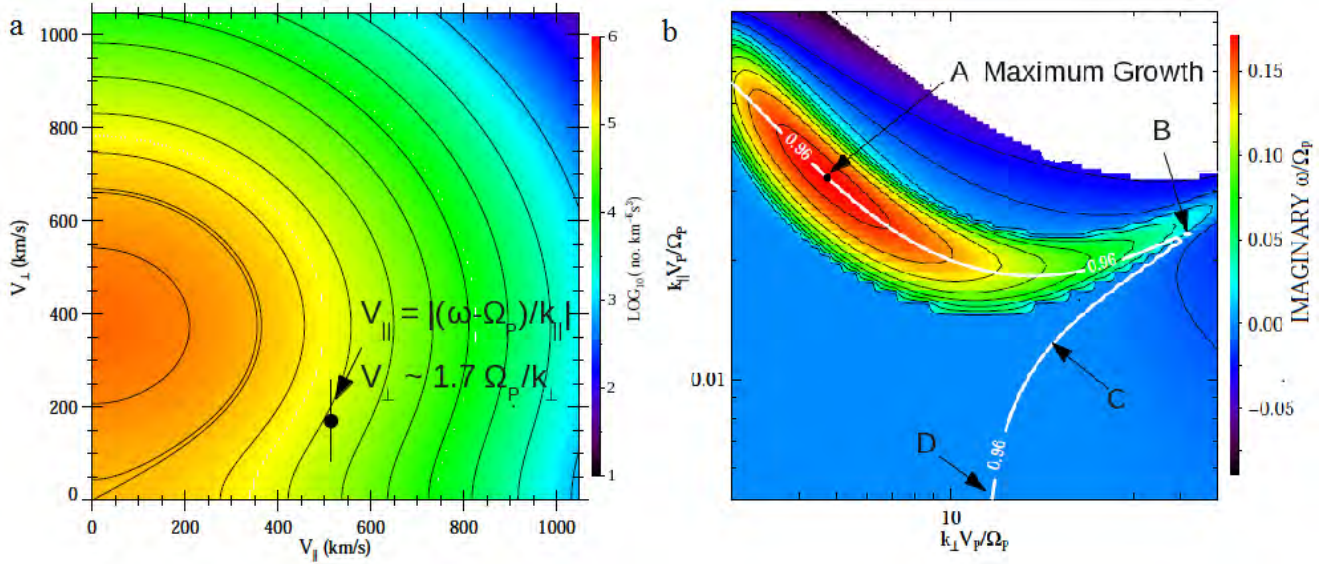

672   Figure 9. (a) A proton distribution function, with a large planetary loss cone, is plotted as a

function of $V_\perp$ and $V_\parallel$, which is used to compute the dispersion relation. The region of maximum

674   interaction of protons with these waves at peak growth is indicated. b) The warm plasma solution

of the index of refraction curve (white) is plotted versus normalized $k_\parallel$ and $k_\perp$ is overlaid on top

676   of the imaginary dispersion surface (red-green growth, blue damping). This curve contains the

peak growth rate (point A). Note that the x-y scales in (b) are different.

678
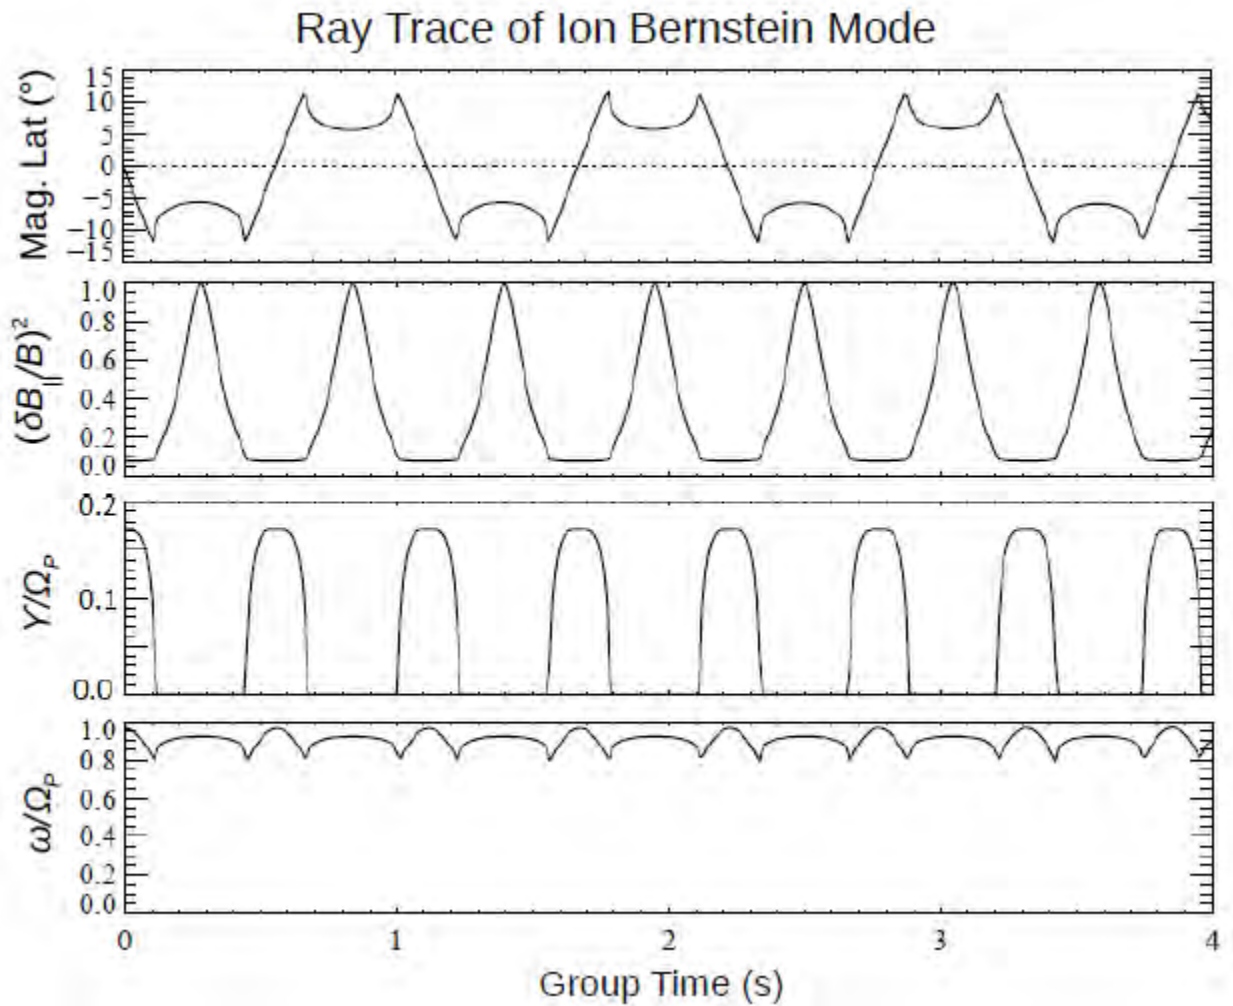

680    Figure 10. Various wave parameters versus group time are plotted.  The ray was launched at the

magnetic equator, at 1.35 $R_M$, at peak growth rate (wave normal angle of 89.61°). Panel a) is the

682    magnetic latitude, b) is the magnetic compressibility, c) is growth rate ($\gamma$), and d) is the wave

frequency ($\omega$) both normalized by the angular proton cyclotron frequency ($\Omega_P$). The magnetic

684    compressibility maximizes off the magnetic equator consistent with observations in Figure Y1.

(Adapted from *Boardsen et al.* [2014])

686

688

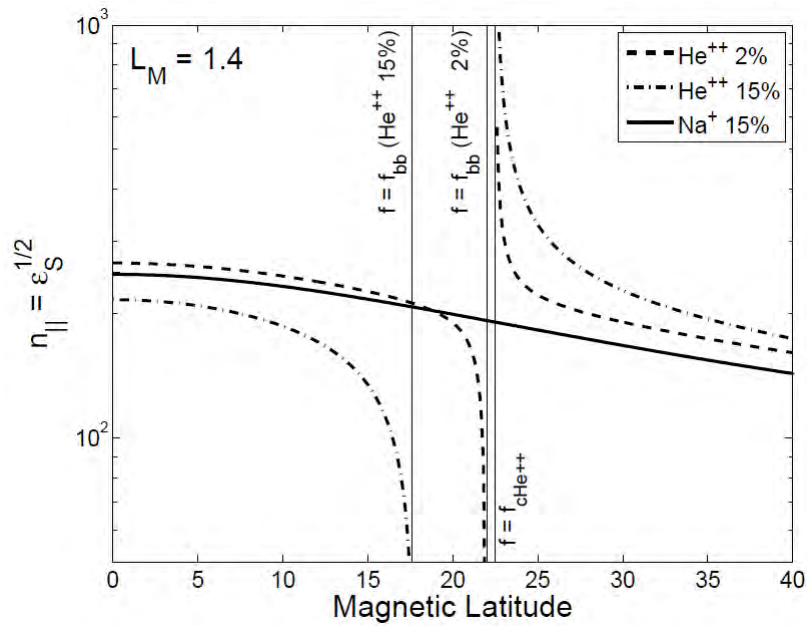

690      Figure 11. The dispersion relation ($n_{\parallel}^2 = \varepsilon_S$) of the IIH waves along the magnetic field line at

L$_M$=1.4 for 2% (dashed) and 15% He$^{++}$ (dotted-dashed) or 15% Na$^+$ (solid lines) plasmas. The

692      stop gap between $f_{bb}$ and $f_{cHe++}$ is clearly seen in this figure.
